Introduction

Healthcare data standards provide shared rules for representing, exchanging, interpreting, and protecting clinical information so that data created in one system can be used safely in another. The standards environment includes messaging specifications, application programming interfaces, clinical terminologies, document structures, imaging formats, identifiers, security mechanisms, and national data sets. Interoperability therefore requires more than moving a file from one organization to another. The receiving system must understand what the data mean, know where they came from, connect them to the correct patient, and present them within a useful workflow. In the United States, the 2026 interoperability environment includes HL7 Version 2 messaging, FHIR APIs, C-CDA documents, DICOM imaging, pharmacy and administrative standards, standardized terminologies, and the United States Core Data for Interoperability. ONC released USCDI Version 7 and the 2026 Interoperability Standards Advisory on July 23, 2026, continuing the national process of defining data elements and implementation standards. Effective interoperability depends on consistent versions, profiles, vocabulary, testing, governance, and data quality rather than on a vendor’s claim that a system “supports” a standard.

Exchange Standards: HL7 Version 2, FHIR, and Clinical Documents

HL7 Version 2 remains widely used for admissions, discharges, transfers, orders, laboratory results, and many other event-driven exchanges. Its maturity and installed base make it difficult and often unnecessary to replace immediately, although local customization can create substantial variation between organizations. Fast Healthcare Interoperability Resources, or FHIR, provides modular resources such as Patient, Observation, Condition, Encounter, and MedicationRequest that can be exchanged through modern API patterns. HL7’s currently published general FHIR specification is R5, version 5.0.0, but real-world regulatory and vendor implementations may require particular versions and implementation guides rather than automatically adopting the newest specification. C-CDA serves a different purpose by supporting persistent clinical documents such as discharge summaries and continuity-of-care records. These approaches can coexist. An application may retrieve discrete

FHIR resources for medication reconciliation while a clinician also receives a complete authenticated document that preserves narrative context. Interoperability succeeds when organizations agree on use cases, profiles, extensions, required fields, search behavior, and testing—not merely when both systems use standards with the same name.

Terminologies, Imaging, Pharmacy, and Administrative Data

Semantic interoperability depends on standardized vocabularies that give clinical concepts stable identifiers and meanings. SNOMED CT supports detailed clinical concepts, LOINC identifies laboratory tests, measurements, and documents, and RxNorm provides normalized names for clinical drugs in the United States. ICD classifications support statistical reporting and reimbursement, while CPT and HCPCS are used for procedures and services in U.S. administrative contexts. These systems are complementary rather than interchangeable; a detailed SNOMED CT problem-list entry may be mapped to an ICD code for reporting, but mapping can lose clinical detail and must be governed carefully. DICOM supports medical imaging and related metadata across radiology and other imaging specialties, while NCPDP standards support pharmacy transactions such as electronic prescribing and claims. X12 is widely used for administrative transactions including eligibility, claims, and payment. Each standard addresses a particular layer of the health-information ecosystem. A laboratory result, for example, may require a LOINC code, a numerical value and unit, a patient identifier, provenance, and an exchange format. Meaning emerges from the combination rather than from any one standard alone.

USCDI, Patient Matching, Provenance, and Data Quality

The United States Core Data for Interoperability defines standardized data classes and elements intended to support nationwide health-information exchange. USCDI specifies what information should be available, while standards such as FHIR or C-CDA define how information may be transmitted. The distinction is important because interoperability can fail even when required data exist if identity, provenance, or context are unreliable. Patient matching commonly uses names, dates of birth, addresses, phone numbers, and other attributes, yet spelling variation, life changes, duplicate records, and incomplete registration can merge two people or split one person across multiple records. Provenance identifies where data originated, who created or transformed them, and when, allowing users to distinguish a clinician-confirmed diagnosis from copied history or patient-reported information. Data quality includes accuracy, completeness, timeliness, consistency, validity, and fitness for purpose. An approximate date may support a clinical conversation while being inadequate for surveillance. Organizations therefore need duplicate-resolution procedures, audit trails, terminology governance, validation rules, and correction workflows. A syntactically perfect message

containing the wrong patient, unit, date, or code remains unsafe.

Security, Consent, Patient Access, and Interoperability Policy

Greater interoperability increases the availability of health information, which can improve care while also expanding privacy and cybersecurity exposure. Systems need strong authentication, role-based authorization, encryption, audit logging, secure API configuration, vendor management, and breach-response procedures. FHIR environments commonly use OAuth-based authorization, but a standard protocol does not guarantee secure implementation. Consent is similarly complex because permissions can vary by jurisdiction, data type, purpose, patient age, proxy relationship, and clinical circumstance. Modern U.S. policy also emphasizes patients' ability to access and direct their electronic health information rather than allowing technical complexity to become an unnecessary barrier. APIs and portals can support this access, but patients need clear correction processes and information about the privacy practices of third-party applications. Organizations must also manage legitimate exceptions involving adolescent confidentiality, sensitive information, or legally permitted restrictions. Interoperability should not mean indiscriminate data release. The goal is to make trustworthy information available to authorized users and patients for appropriate purposes while maintaining transparent controls over how data are used, shared, corrected, and audited.

Clinical Workflow, Implementation, and Governance

Standards create value only when they fit clinical workflow. Nurses, physicians, pharmacists, laboratories, health-information managers, developers, security staff, patients, and operational leaders should participate in implementation because each group sees different risks. Overly rigid templates can turn nursing documentation into checkbox work, while poorly designed interfaces can force duplicate entry or bury critical information. Clinical decision support also depends on standardized data: allergy alerts require coded substances and reactions, medication rules require dose and renal-function context, and quality measures require consistent definitions. Implementation should begin with a defined use case and measurable outcome, followed by system inventory, version selection, terminology mapping, conformance testing, realistic edge cases, production monitoring, and change management. Legacy systems will remain part of healthcare for years, so organizations often need interface engines and mappings rather than one immediate replacement project. Governance should document definitions and ownership, review local codes, manage version changes, and investigate data-quality failures without simply blaming users. Training matters because staff need to understand why standardized entry affects downstream care, reporting, analytics, and patient safety.

Conclusion

Healthcare interoperability depends on a layered standards ecosystem rather than one universal format. HL7 Version 2, FHIR, C-CDA, DICOM, NCPDP, X12, SNOMED CT, LOINC, RxNorm, ICD, and USCDI serve different purposes across clinical, imaging, pharmacy, administrative, and national exchange workflows. In 2026, USCDI Version 7 and the updated Interoperability Standards Advisory continue to define the U.S. data-sharing landscape, while FHIR provides modern API capabilities alongside established messaging and document standards. The technical specifications are only the beginning. Safe exchange requires accurate patient matching, provenance, terminology governance, privacy, authorization, auditability, workflow design, and continuous data-quality monitoring. A standard cannot make incorrect information trustworthy or guarantee that a clinician can use the information efficiently. Organizations therefore should evaluate interoperability by outcomes: whether authorized users receive accurate, interpretable information at the right time, whether patients can access and correct their records, and whether systems reduce rather than multiply manual reconciliation. The ultimate objective is not maximum data movement. It is dependable information exchange that improves continuity, safety, patient participation, public health, and responsible reuse.
