Introduction

Smoking during pregnancy affects more than the pregnant person because nicotine, carbon monoxide, and other tobacco-smoke constituents can alter the biological environment in which the fetus develops. The Centers for Disease Control and Prevention states that smoking before or during pregnancy is associated with fetal growth restriction, low birth weight, preterm delivery, placental complications, adverse effects on developing lungs and brain, stillbirth, and sudden infant death syndrome (CDC, 2025a). Research has also examined whether prenatal tobacco exposure may influence the newborn brain's early response to speech sounds. That question is important because auditory discrimination begins before birth and supports later language learning, but the evidence must be interpreted cautiously. A difference in newborn brain responses does not prove that every exposed child will develop a language disorder. It identifies a possible developmental pathway that warrants prevention and further study. The strongest public-health response combines accurate risk communication with compassionate cessation support, smoke-free homes, and follow-up rather than shame or moral judgment.

How Tobacco Exposure Reaches the Fetus

The fetus depends on maternal circulation and the placenta for oxygen and nutrients, so chemicals absorbed through the lungs can influence fetal development even though smoke itself does not literally enter the uterus in the way it fills a room. Carbon monoxide binds strongly to hemoglobin and can reduce oxygen delivery, while nicotine affects blood vessels and crosses the placenta. Tobacco smoke also contains numerous toxic compounds that can contribute to oxidative stress, inflammation, and altered placental function. CDC guidance continues to identify smoking during pregnancy as a cause of fetal growth restriction and low birth weight and as a risk factor for preterm birth, placental complications, and damage to developing lungs and brain (CDC, 2025a). These mechanisms help explain why the concern extends beyond birth weight alone. Developmental effects may involve several systems at once, including respiratory, cardiovascular, neurological, and placental processes. Because exposure level, timing, genetics, nutrition, stress, and other conditions vary, risk should be described probabilistically rather than as a guaranteed outcome.

Speech Processing and the Newborn ERP Study

Newborn infants do not understand words in the way older children do, but their auditory systems can detect differences in rhythm, timing, pitch, and speech sounds. Researchers can study this early processing with electroencephalography and event-related potentials, which record small changes in electrical activity after a sound is presented. Key and colleagues compared newborns with and without reported prenatal tobacco exposure and found group differences in responses to speech stimuli, suggesting that exposure may influence early auditory processing (Key et al., 2007). The study is valuable because it examines neural responses soon after birth rather than waiting for later language tests, yet its limitations are equally important. The sample was relatively small, exposure measurement was not sufficiently detailed to establish a precise dose-response relationship, and other maternal or social factors could influence development. An ERP difference is therefore neither a diagnosis nor a prediction of an individual child's future. It is evidence of a possible developmental effect that should be considered alongside the much stronger established evidence on pregnancy and infant health.

Secondhand Smoke and the Infant Environment

Risk continues after delivery when infants are exposed to secondhand smoke in homes, vehicles, or other enclosed spaces. CDC states that there is no safe level of secondhand-smoke exposure and links infant exposure with sudden infant death syndrome, lower respiratory illness, middle-ear disease, decreased lung function, and asthma attacks (CDC, 2025b). Opening a window, smoking in another room, or using ventilation cannot provide complete protection because smoke and fine particles move through indoor air. Residue from tobacco smoke can also settle on clothing, furniture, walls, and other surfaces, creating additional exposure concerns for infants who touch and mouth objects. Prevention should therefore focus on a fully smoke-free home and vehicle rather than on partial separation. Household members matter as well as the pregnant or postpartum parent. A person trying to quit is more likely to struggle when a partner or relative continues smoking nearby. Family-centered plans can remove cigarettes and ashtrays, establish smoke-free rules, identify triggers, and connect every smoker who wants help with cessation support.

Cessation Support Without Stigma

Pregnancy creates an important opportunity for smoking cessation, but communication should avoid humiliation because nicotine dependence is a health condition shaped by addiction, stress, mental health, social networks, and access to care. Fear of judgment can cause patients to underreport tobacco use or avoid discussing relapse. Clinicians should ask respectfully about cigarettes, e-cigarettes, heated tobacco products, and other nicotine sources; explain known risks; assess readiness to quit; and offer repeated support. CDC guidance emphasizes that quitting at any time

during pregnancy can improve health outcomes, with earlier cessation providing greater benefit (CDC, 2025a). Behavioral counseling, quitlines, text support, and structured follow-up can help, while medication decisions should be individualized with a qualified healthcare professional because pregnancy changes the balance of risks and benefits. The goal is not to demand perfect behavior as a condition of receiving care. It is to reduce exposure as effectively as possible, support repeated quit attempts, and continue assistance after birth when sleep deprivation and household stress may increase relapse risk.

Environmental and Community Health Implications

Tobacco use also has environmental consequences through cultivation, manufacturing, packaging, transport, indoor air contamination, and discarded cigarette filters. Filters contain cellulose acetate, a plastic material that can persist in the environment and fragment into smaller particles. Cigarette butts left on streets, beaches, playgrounds, or household surfaces can release nicotine and other contaminants and may be picked up by children. Community-health education should therefore combine cessation messages with smoke-free public spaces, litter prevention, safe disposal, and accurate information about secondhand exposure. Educational materials are most useful when they provide verified local referral pathways rather than copied telephone numbers or addresses that may be outdated. They should also recognize that people may use nicotine products without describing themselves as smokers. A good program asks about product type, household exposure, work exposure, and barriers to quitting, then connects individuals with appropriate support. Environmental protection and maternal-child health reinforce one another because reducing tobacco use lowers both direct biological exposure and the wider burden created by tobacco waste.

Conclusion

Smoking during pregnancy is associated with well-established risks to fetal and infant health and may also influence the newborn brain’s early processing of speech sounds. The event-related-potential study by Key and colleagues provides evidence of group-level differences in auditory processing, but it should not be interpreted as proof that prenatal exposure inevitably produces a language disorder. The stronger and more consistent evidence concerns fetal growth, preterm birth, placental complications, lung and brain development, and infant risks from secondhand smoke. Current CDC guidance also makes clear that quitting during pregnancy is beneficial and that smoke-free homes and vehicles protect infants after birth (CDC, 2025a; CDC, 2025b). Effective prevention therefore requires more than warning labels. It requires respectful screening, repeated cessation support, household involvement, clear digital and community education, and follow-up after delivery. The appropriate public-health message is firm about risk while remaining supportive toward people who are dealing with nicotine dependence and attempting to reduce harm.
