Introduction

Evidence-based practice improves healthcare when practitioners combine credible research with clinical expertise, patient preferences, and the realities of the local setting. The Stetler Model was developed to help nurses and other practitioners make that combination deliberately rather than treating published research as an automatic command to change practice. First introduced in the 1970s and updated as evidence-based practice matured, the model emphasizes practitioner judgment and can be used by an individual clinician, a small clinical group, or a larger organizational initiative (Stetler, 2001). Its enduring value lies in separating several decisions that are often collapsed together: whether evidence is methodologically credible, whether it addresses the local problem, whether the proposed change is feasible, how it should be translated into practice, and whether implementation actually improves outcomes. The model also recognizes that evidence comes from more than journals. Internal quality data, patient feedback, incident reports, workflow observations, and staff experience can reveal whether a problem exists locally and how a research-supported intervention must be adapted. The Stetler Model is therefore best understood as a structured reasoning process for responsible evidence use.

Preparation and Validation of Evidence

The preparation phase begins by defining the problem, purpose, stakeholders, and decision that must be made. A unit may be concerned about falls, pain reassessment, delayed sepsis recognition, staff retention, or inconsistent discharge teaching, but the team should describe the current practice before selecting a favored solution. A focused clinical question can organize searching, while early stakeholder involvement reveals operational, ethical, financial, and patient concerns that might otherwise appear late as “resistance.” Validation then asks whether each evidence source deserves confidence. Randomized trials require appraisal of allocation, attrition, outcome measurement, and applicability; qualitative studies require attention to sampling, analysis, reflexivity, and credibility; guidelines should disclose how evidence was searched and graded; and local data require dependable definitions and collection. A large quantity of publications does not create strong evidence when studies are biased or answer a different question. Appraisal should be proportionate to risk, but practitioners must still distinguish statistical significance from clinical importance and understand uncertainty before moving from literature to action (Melnyk & Fineout-Overholt, 2019).

Comparative Evaluation and Decision Making

After individual sources are appraised, the practitioner compares the evidence as a whole and evaluates it against patient needs and local conditions. Studies may disagree because of differences in population, intervention intensity, staff expertise, setting, outcome definitions, or implementation quality. The purpose of comparative evaluation is therefore not to average conflicting findings mechanically but to identify the circumstances under which an intervention appears beneficial, harmful, or uncertain. Internal evidence becomes especially important at this stage. A hospital may know from external research that multifactorial fall prevention is effective, yet local incident data may show that most falls occur during toileting on evening shifts, indicating where adaptation should focus. The decision can be adoption, adaptation, a limited pilot, continued observation, or rejection. Choosing not to change practice can be evidence based when benefit is weak, risk is unacceptable, or the intervention conflicts with patient values. Conversely, feasibility barriers should not automatically end a promising project when they can be addressed through training, staffing, technology, or leadership support. The rationale should be documented so that later reviewers can distinguish evidence-based judgment from personal preference.

Translation and Application in Clinical Settings

Translation converts an evidence-supported decision into work that clinicians can perform reliably. Research papers describe interventions in scientific terms, but staff need clear responsibilities, workflows, documentation, equipment, training, and escalation procedures. The implementation team must identify which elements are essential to the intervention's effectiveness and which can be adapted without changing its function. Translation may therefore involve revised protocols, electronic prompts, competency assessment, patient education, staffing changes, or a pilot period before full adoption. Application can occur at different levels. An individual nurse may change a personal decision process when it remains within scope and policy, while a unit-wide or hospital-wide change requires governance, communication, and monitoring. Staff should be able to report confusion and unintended consequences without being labeled resistant, because implementation problems often reveal defects in the design rather than defects in motivation. A presentation or training session is not evidence of successful application by itself. The new practice must become feasible within ordinary workflow and produce observable changes in behavior or outcomes (Stetler, 2001).

Evaluation, Learning, and Sustainability

Evaluation determines whether the evidence was used as intended and whether the change produced the expected benefit. Process measures answer whether the new practice actually occurred, outcome measures examine effects on patients, staff, cost, or quality, and balancing measures detect unintended consequences. A fall-prevention project, for example, might monitor injurious falls as an

outcome, completion of individualized plans as a process measure, and unnecessary mobility restriction as a balancing measure. Evaluation should be designed during preparation rather than added after implementation because baseline data and comparison periods may otherwise be lost. When outcomes do not improve, the correct conclusion is not automatically that the research was wrong. The intervention may have been delivered inconsistently, the local population may differ from study participants, or another simultaneous change may have affected the measure. Conversely, apparent improvement may reflect seasonality or random variation. Repeated measurement, transparent feedback, and review of implementation fidelity allow teams to decide whether a practice should be maintained, modified, expanded, or discontinued. In this way, the Stetler Model creates a cycle of learning rather than a one-time evidence project.

Strengths, Limitations, and Staff Development

The Stetler Model is especially useful because it is flexible, practitioner oriented, and compatible with clinical, educational, and managerial questions. Its distinction between validation and comparative evaluation helps users separate methodological quality from local usefulness, while its inclusion of internal evidence prevents research literature from being treated as sufficient context. Romp and Kiehl's staff-development application illustrates that the model can guide educational change as well as direct patient care by linking preparation, appraisal, translation, implementation, and evaluation to workforce outcomes (Romp & Kiehl, 2009). The same flexibility can also be a limitation. Because the model depends heavily on practitioner judgment, the quality of decisions varies with appraisal skill, protected time, database access, authority, mentorship, and organizational culture. It does not provide every operational tool required for project management, stakeholder analysis, or implementation science, so teams may need complementary frameworks and quality-improvement methods. Reviews of evidence-based practice models therefore describe the Stetler Model as valuable but not self-sufficient for every organizational change problem (Schaffer et al., 2013).

Conclusion

The Stetler Evidence-Based Practice Model offers a disciplined way to move from a clinical or organizational problem to responsible evidence use. Preparation clarifies the question and context; validation establishes how much confidence individual sources deserve; comparative evaluation integrates findings with local evidence and patient needs; translation converts the decision into practical workflows; and evaluation determines whether the change was implemented and produced worthwhile outcomes. This sequence protects healthcare teams from two opposite errors: continuing a practice merely because it is familiar and adopting a new intervention merely because it has been published. The model's practitioner orientation also supports smaller decisions that may never become formal system-wide projects, while its use of internal evidence keeps implementation connected to local reality. Its limitations are equally important because evidence-based practice requires time, appraisal skill, leadership support, and operational tools that the model cannot provide

automatically. Used within a supportive organization, the Stetler framework helps clinicians move beyond tradition without abandoning professional judgment, making practice change a transparent process of appraisal, adaptation, measurement, and learning.
