Global Fibre Use and Merino Wool Properties

Posted on October 17, 2019

Thousands of tonnes of cotton and wool fibre is produced each year. For instance, in 2019, the world produced an estimated 25.9 million tonnes of cotton fibre, 1.1 million tonnes of wool fibre, and substantially larger volumes of man-made cellulosic and synthetic fibres; the global fibre market therefore contains several distinct natural and manufactured material streams rather than one uniform textile input. (The Fiber Year Consulting, n.d.; International Wool Textile Organisation, n.d.) Natural fibres are obtained from plants and animals, while synthetic and regenerated fibres are produced through industrial processes. This paper examines cotton and wool, with particular emphasis on Australian Merino wool, and discusses production, trade, employment, environmental characteristics, and fibre properties.

Wool Fibers

Wool is a natural protein fibre obtained primarily from sheep. Different sheep breeds produce fibres with different diameters, lengths, crimp, strength, colour, and suitability for end products. Fine Merino wool is particularly valued for apparel because it can be soft enough to wear next to the skin, while broader wools are commonly used for carpets, interiors, and heavier textiles. (International Wool Textile Organisation, n.d.)

Wool is renewable because sheep grow a new fleece each year, and it is biodegradable under suitable conditions. The fibre can absorb water vapour without immediately feeling wet, has natural elasticity and crimp, and tends to resist odour because of its moisture-management characteristics. Wool also has a relatively high ignition temperature and tends to self-extinguish when the flame source is removed, properties that make it useful in some interior and protective-textile applications. (International Wool Textile Organisation, n.d.)

Wool production nevertheless has environmental impacts. Sheep require land, feed, water, veterinary care, fencing, and transport, and ruminant livestock produce methane. The environmental performance of a wool system therefore depends on grazing management, biodiversity, animal health, productivity, processing energy, transport, product longevity, and end-of-life pathways. A material should not be described as sustainable solely because it is natural.

Cotton Fibers

Cotton is a natural cellulose fibre that grows around the seeds of plants in the genus *Gossypium*. After harvesting, ginning separates the lint from seeds and other material. Cotton fibres are then cleaned, carded, combed where required, spun into yarn, and manufactured into woven or knitted products.

Cotton is widely used because it is comfortable, absorbent, washable, and compatible with many dyeing and finishing processes. The crop is produced in regions with different climates and irrigation systems, which means that environmental performance varies considerably. Water consumption, pesticide use, soil health, energy, labour conditions, fibre yield, and processing efficiency all influence the sustainability of cotton production.

World Textile Fibre Demand

Fibre Category	General Market Role
Cotton	Major natural fibre used in apparel, home textiles, and industrial products
Wool	Smaller-volume natural fibre concentrated in apparel, interiors, and technical uses
Man-made cellulosics	Regenerated fibres such as viscose, modal, and lyocell
Synthetics	Large-volume fibres including polyester, nylon, acrylic, and polypropylene

Global fibre demand has increasingly been dominated by synthetic fibres, especially polyester, while cotton remains the largest natural fibre by volume and wool represents a relatively small but high-value segment. Production figures vary by year and by the definitions used for staple, filament, recycled, and specialty fibres, so market comparisons should identify the data source and reporting period. (The Fiber Year Consulting, n.d.)

World Production of Cotton and Wool

Cotton production is concentrated in countries including China, India, the United States, Brazil, Pakistan, Turkey, and others, although rankings shift between seasons. Production depends on weather, planted area, irrigation, yields, prices, pests, policy, and trade conditions. Cotton is traded globally both as raw fibre and through yarn, fabric, garments, and made-up textile products.

Wool production is geographically diverse, with important sheep industries in Australia, China, New Zealand, South Africa, Argentina, Uruguay, the United Kingdom, and other countries. Australia is particularly important in fine apparel wool and Merino production. Wool statistics may refer to greasy wool, clean wool, or wool at different processing stages; direct comparisons should therefore use consistent units. (International Wool Textile Organisation, n.d.)

Wool Production in Australia

Australia has a long history of sheep and wool production and is internationally associated with Merino wool. Australian production systems range from extensive pastoral enterprises to mixed farms that combine sheep with cropping or other livestock. Fleece value depends on fibre diameter, staple strength, length, vegetable matter, colour, yield, contamination, certification, and market demand.

Merino sheep produce highly crimped fine fibres. Micron measurement is important because fibre diameter strongly influences handle and end use. Finer fibres generally command premiums when market conditions favour luxury and next-to-skin apparel, although price is also affected by other quality attributes and by global demand. (International Wool Textile Organisation, n.d.)

Merino Wool Properties

Merino wool is valued for a combination of softness, elasticity, moisture buffering, odour resistance, thermal regulation, and drape. The fibre's natural crimp creates air spaces in yarn and fabric, supporting insulation, while its protein structure can absorb moisture vapour. Fine Merino fibres bend more easily against the skin than broad wool fibres, reducing the prickling sensation associated with coarser wools. (International Wool Textile Organisation, n.d.)

Wool fibres have overlapping cuticle scales, a cortex that provides much of the fibre's mechanical behaviour, and in some coarse fibres a medulla. The complex keratin structure contributes resilience and allows wool products to recover from deformation. Chemical and mechanical processing can modify shrink resistance, softness, lustre, dye uptake, and performance.

Wool and Fire Performance

Wool generally requires more oxygen to sustain combustion than many common fibres, has a high ignition temperature, produces less melting and dripping than thermoplastic synthetics, and tends to char and self-extinguish when the ignition source is removed. These characteristics are useful in interiors, aircraft, transport, military, and protective-textile contexts. Fire performance nevertheless depends on fabric construction, finishes, blends, mass, ventilation, and the applicable test method. (International Wool Textile Organisation, n.d.)

Moisture Management

Wool can absorb substantial water vapour into the fibre structure while the surface may still feel comparatively dry. This moisture buffering can help regulate the microclimate between the body and clothing. The absorption process can release heat, while desorption can have a cooling effect. These

properties contribute to comfort across changing environmental conditions. (International Wool Textile Organisation, n.d.)

Odour Resistance

Wool garments often require less frequent washing than some alternatives because the fibre can absorb moisture vapour and certain odour molecules. Reduced washing may lower water and energy use during the use phase, although actual benefits depend on consumer behaviour, washing equipment, detergent, drying, garment durability, and product lifetime. (International Wool Textile Organisation, n.d.)

Biodegradability and Circularity

Wool is biodegradable under conditions that allow microorganisms to break down its protein structure. It can also be reused and recycled through garment resale, fibre recovery, mechanical recycling, and other pathways. Recycling may shorten fibres and alter quality, so recovered wool can be blended or used in applications suited to shorter fibres. Product durability and reuse are often important because extending the useful life of a garment can reduce demand for replacement products. (International Wool Textile Organisation, n.d.)

Cotton Production in India and Pakistan

India and Pakistan have long histories of cotton cultivation, spinning, weaving, garment manufacturing, and textile trade. Their textile sectors connect farmers, ginners, spinners, weavers, processors, garment factories, exporters, logistics companies, and domestic retailers.

The industry also faces challenges involving water, energy, pollution control, labour standards, productivity, technology, raw-material quality, and international competition. Human-resource practices and institutional conditions influence how firms recruit, train, compensate, and retain workers, and management systems often differ between local firms and multinational enterprises. (Budhwar & Khatri, 2001; Budhwar & Sparrow, 2002)

Textile Employment

Textile and apparel supply chains generate employment across agriculture, manufacturing, trade, transport, design, retail, and services. Jobs range from seasonal farm labour and machine operation to quality control, engineering, merchandising, logistics, marketing, and management.

Employment quality varies. Risks can include low pay, insecure contracts, excessive hours, hazardous

chemicals, dust, repetitive work, fire safety, and weak worker representation. Competitiveness should therefore be evaluated alongside occupational safety, wages, gender equality, social protection, and freedom of association.

Labour and Human Resource Management

Human-resource systems influence productivity and worker wellbeing through recruitment, training, performance management, compensation, industrial relations, and career development. Studies of Indian organizations have shown that HRM practices are shaped by institutional, cultural, and ownership contexts, and multinational firms may transfer some global practices while adapting others locally. (Budhwar & Sparrow, 2002)

Comparisons between Indian and British firms have also demonstrated that national context influences strategic HR choices. This matters in textile supply chains because a single global buyer may source from factories with very different labour markets, management traditions, and regulatory environments. (Budhwar & Sparrow, 2002)

Research comparing Indian and British-owned firms in India similarly suggests that ownership and institutional setting can shape HR practices. Buyers should therefore avoid assuming that a written supplier code produces identical management behaviour across every site. (Budhwar & Khatri, 2001)

Australian Wool Supply Chain

The wool supply chain begins with sheep breeding, grazing management, animal health, shearing, classing, testing, sale, transport, scouring, topmaking, spinning, weaving or knitting, finishing, garment manufacture, retail, use, reuse, and end of life. Many Australian wool enterprises specialize in producing greasy wool, while much downstream processing occurs internationally.

Quality information is important because buyers need to understand fibre diameter, yield, staple strength, vegetable matter, and other characteristics. Testing and auction systems help translate biological variation into commercial specifications.

Sheep Welfare

Animal welfare is an important part of wool sustainability. Good husbandry includes nutrition, water, shelter appropriate to conditions, disease prevention, parasite control, safe handling, skilled shearing, pain management where required, and timely treatment of injury.

Public debate has focused particularly on flystrike prevention and mulesing. Producers, industry bodies, brands, animal-welfare groups, and researchers have promoted different strategies involving

genetics, breech management, insect control, pain relief, and non-mulesed production. Market claims should be supported by credible documentation.

Grazing and Land Management

Sheep production occurs across diverse Australian environments. Sustainable grazing requires matching stocking rates to pasture growth, protecting soil, managing water, maintaining ground cover, controlling weeds and pests, and conserving biodiversity. Poor grazing management can contribute to erosion and land degradation, while well-managed grazing systems can maintain productive landscapes.

Environmental claims should use farm-level evidence because rainfall, soil, vegetation, stocking intensity, and management vary greatly between properties.

Climate Impacts

Sheep produce methane through enteric fermentation. Climate assessment of wool must also consider feed production, land management, energy, transport, processing, product use, and product lifetime. Allocating impacts between wool and meat can materially change life-cycle results.

Research and industry programs are exploring genetics, feed strategies, productivity, carbon sequestration, renewable energy, and improved land management. Claims of carbon neutrality require transparent boundaries, calculation methods, and treatment of offsets.

Water Use

Water is required for livestock, pasture, cleaning, wool scouring, dyeing, finishing, and garment care. The environmental significance depends on location and water scarcity. A litre used in a water-abundant region is not equivalent to a litre removed from a highly stressed basin.

Processing facilities can reduce impacts through water recycling, efficient machinery, chemical recovery, wastewater treatment, and improved dyeing technologies.

Wool Scouring

Greasy wool contains lanolin, dirt, sweat salts, and vegetable matter. Scouring washes the fibre before later processing. The operation produces wastewater containing organic matter and detergents, requiring treatment.

Lanolin can be recovered as a useful co-product for cosmetics, pharmaceuticals, lubricants, and other

applications. Efficient recovery improves resource use and reduces waste.

Dyeing and Finishing

Textile dyeing and finishing can involve water, heat, salts, dyes, surfactants, and specialty chemicals. Environmental performance depends on the chemistry, equipment, wastewater controls, energy source, and process efficiency.

Certification and restricted-substance programs can support safer chemical management, but certification should be understood as evidence of conformance to defined requirements rather than proof that the entire product has no environmental impact.

Quality and Durability

Durability is a significant sustainability factor. A garment that remains useful for many years may distribute manufacturing impacts across a longer service life. Wool's resilience and odour resistance can support extended wear, while careful washing, repair, and storage can preserve products. (International Wool Textile Organisation, n.d.)

Durability depends on yarn, fabric construction, garment design, abrasion, pilling, laundering, moth protection, and consumer care. High-quality fibre alone does not guarantee a long-lasting garment.

Merino Apparel

Fine Merino wool is used in base layers, knitwear, suits, socks, outdoor garments, and luxury fashion. The fibre's moisture management and temperature-regulation characteristics make it suitable for activewear, while softness supports next-to-skin use. (International Wool Textile Organisation, n.d.)

Blends combine wool with synthetics, cotton, silk, or cellulosics to modify stretch, strength, drying, cost, handle, or durability. Blend performance should be assessed for the intended use, including implications for recycling.

Technical Textiles

Wool can be used in acoustic products, insulation, bedding, interiors, transportation, protective applications, and filtration. Natural crimp supports bulk and sound absorption, while fire behaviour can be valuable in interior environments. (International Wool Textile Organisation, n.d.)

Technical applications require testing against specific standards. Natural fibre origin does not eliminate the need for performance verification.

Carpets and Interior Products

Broader wool fibres are commonly used in carpets and upholstery. Wool carpet can provide resilience, appearance retention, sound absorption, and fire performance. Product life can be long when construction and maintenance are appropriate. (International Wool Textile Organisation, n.d.)

End-of-life pathways remain a challenge because backing, adhesives, blends, contamination, and collection systems affect recyclability.

Consumer Care

Wool care labels should be followed because agitation, heat, and moisture can cause felting or shrinkage in untreated products. Modern shrink-resistant treatments and washing-machine wool cycles allow easier care for many garments.

Consumers can reduce impacts through less frequent washing when hygienically appropriate, full loads, cool water, efficient equipment, line drying where practical, repair, resale, and donation.

Lavender and Diversified Farm Enterprises

Some rural enterprises diversify beyond conventional livestock or cropping into tourism, specialty crops, farm-gate retail, and value-added products. Lavender farms are one example. Blue Mountain Lavender Farm in Australia illustrates how a small agricultural business can combine cultivation with direct sales and visitor experiences. (Blue Mountain Lavender Farm, n.d.)

Diversification can provide additional revenue but also requires marketing, food or cosmetic compliance where relevant, customer service, labour, insurance, and seasonal planning.

Australian Cattle Stations and Pastoral Context

Large Australian pastoral properties demonstrate the scale and geographic diversity of livestock production. Cattle-station operations may cover extensive areas and depend on water infrastructure, transport, seasonal conditions, animal health, labour, and remote logistics. (Cattle Stations, n.d.)

Although cattle and wool are different industries, both operate within broader pastoral systems where land condition, drought, biodiversity, labour supply, and market access are important management issues.

Trade and Market Volatility

Natural-fibre prices respond to exchange rates, fashion, inventories, weather, economic growth, consumer confidence, synthetic-fibre prices, and trade policy. Wool markets can be especially volatile because production is relatively small compared with global synthetic-fibre demand.

Producers manage risk through quality improvement, diversified income, financial planning, forward contracts where available, and market information. No individual farm can control global demand.

Traceability

Brands increasingly seek information about fibre origin, animal welfare, environmental management, and processing. Traceability systems can connect farm lots with later stages, but the level of traceability varies.

Digital records, certification, chain-of-custody controls, testing, and commercial documentation can help. Claims should distinguish identity-preserved fibre from mass-balance or certificate-based systems.

Certification

Textile certifications may address organic production, animal welfare, chemical management, recycled content, environmental practices, labour, or chain of custody. Each scheme has its own scope and audit methodology.

Certification is most useful when customers understand what it verifies. One logo should not be interpreted as proof of every social and environmental attribute.

Innovation in Wool

Innovation includes machine-washable treatments, lightweight fabrics, seamless knitting, digital traceability, new blends, performance apparel, recycling, and finishing technologies. Research also examines ways to improve sheep genetics, fibre quality, animal health, and environmental performance. (International Wool Textile Organisation, n.d.)

Innovation should be evaluated across the full life cycle because a treatment that improves durability may also introduce additional chemistry or processing.

Synthetic Competition

Polyester and other synthetic fibres dominate global fibre production because they are inexpensive, scalable, strong, and adaptable. Natural fibres compete through performance, comfort, renewable origin, cultural value, and market positioning. (The Fiber Year Consulting, n.d.)

Comparisons should avoid simplistic claims. Synthetic fibres are associated with fossil feedstocks and microplastic concerns, while natural fibres can have land, water, methane, chemical, and labour impacts. The best material depends on application, production method, durability, care, and end of life.

Microfibres

All textiles can shed fibres during manufacture, wear, and washing. Synthetic fibres persist as plastic in the environment, while natural fibres biodegrade more readily under suitable conditions, though dyes and finishes may influence environmental behaviour.

Reducing shedding can involve better yarn and fabric construction, washing practices, filtration, and product durability.

Recycling Wool

Wool has a long history of mechanical recycling. Used garments and manufacturing waste can be sorted, shredded, and respun, often in blends. Recycled fibre can be used in blankets, apparel, insulation, and other products. (International Wool Textile Organisation, n.d.)

Design for disassembly, fibre identification, collection infrastructure, and reduced use of incompatible blends can improve circularity.

Economic Value Versus Volume

Wool represents a small share of global fibre volume but can achieve high value per kilogram, particularly in fine apparel categories. Volume-based comparisons can therefore underestimate its economic significance. (The Fiber Year Consulting, n.d.; International Wool Textile Organisation, n.d.)

Premium value depends on quality, reputation, traceability, design, processing, branding, and consumer willingness to pay.

Future of Natural Fibres

Natural fibres will continue to compete within a rapidly changing textile market influenced by population, income, climate policy, recycling requirements, consumer preferences, and technological innovation. Cotton and wool have established supply chains and distinctive performance characteristics, but producers will face increasing expectations for transparency and measurable environmental and social performance.

Future competitiveness is likely to depend on productivity, quality, traceability, durability, credible sustainability claims, and collaboration across farming, processing, manufacturing, retail, and recycling.

Conclusion

Cotton and wool are important natural fibres with very different biological, technical, and market characteristics. Cotton is produced at much greater volume and is central to global apparel and home-textile supply chains. Wool represents a smaller segment but offers properties such as crimp, elasticity, moisture management, odour resistance, biodegradability, and fire performance. Australian Merino wool is particularly important in fine apparel. (The Fiber Year Consulting, n.d.; International Wool Textile Organisation, n.d.)

The sustainability of either fibre cannot be judged from natural origin alone. Cotton systems may involve irrigation, pesticides, labour, and soil impacts, while wool involves land, methane, animal welfare, processing, and transport. Product lifetime, care, reuse, recycling, and end of life also influence performance.

A resilient textile industry requires reliable data, responsible labour practices, environmental management, innovation, and transparent supply chains. Rather than treating wool, cotton, and synthetic fibres as universally good or bad, producers and consumers should evaluate materials according to their specific application and full life cycle.
